## ABSTRACT

We present the results from the *Suzaku* X-ray observations of five flat-spectrum radio quasars (FSRQs), namely PKS 0208–512, Q 0827+243, PKS 1127–145, PKS 1510–089 and 3C 454.3. All these sources were additionally monitored simultaneously or quasi-simultaneously by the *Fermi* satellite in gamma-rays and the *Swift* UVOT in the UV and optical bands, respectively. We constructed their broad-band spectra covering the frequency range from  $10^{14}$  Hz up to  $10^{25}$  Hz, and those reveal the nature of high-energy emission of luminous blazars in their low-activity states. The analyzed X-ray spectra are well fitted by a power-law model with photoelectric absorption. In the case of PKS 0208–512, PKS 1127–145, and 3C 454.3, the X-ray continuum showed indication of hard-

ening at low-energies. Moreover, when compared with the previous X-ray observations, we see a significantly increasing contribution of low-energy photons to the total X-ray fluxes when the sources are getting fainter. The same behavior can be noted in the *Suzaku* data alone. A likely explanation involves a variable, flat-spectrum component produced via inverse-Compton (IC) emission, plus an additional, possibly steady soft X-ray component prominent when the source gets fainter. This soft X-ray excess is represented either by a steep power-law (photon indices  $\Gamma \sim 3 - 5$ ) or a blackbody-type emission with temperatures  $kT \sim 0.1 - 0.2$  keV. We model the broad-band spectra of the five observed FSRQs using synchrotron self-Compton (SSC) and/or external-Compton radiation (ECR) models. Our modeling suggests that the difference between the low- and high-activity states in luminous blazars is due to the different total kinetic power of the jet, most likely related to varying bulk Lorentz factor of the outflow within the blazar emission zone.

*Subject headings:* galaxies: active — quasars: jets — radiation mechanisms: non-thermal — X-rays: galaxies

## 1. Introduction

Observations with the EGRET instrument (30 MeV to 30 GeV; Thompson et al. 1993) on board the Compton Gamma-Ray Observatory (CGRO) have resulted in detection of  $\gamma$ -ray emission from a few hundred astrophysical sources, 66 of which were securely associated with active galactic nuclei (AGNs; e.g., Hartman et al. 1999). Most of the AGNs detected by EGRET show characteristics of the blazar class. Observationally, this class include flat-spectrum radio quasars (FSRQs) and BL Lac objects. FSRQs have strong and broad optical emission lines, while the lines are weak or absent in BL Lacs. During the first three months of the *Fermi* Large Area Telescope’s (LAT) all-sky-survey, 132 bright sources at high Galactic latitudes ( $|b| > 10^\circ$ ) were detected at a confidence level greater than  $10\sigma$  (Abdo et al. 2009a). As expected from the EGRET observations, a large fraction (106) of these sources have been associated with known AGNs (Abdo et al. 2009b). This includes two radio galaxies (Centaurus A and NGC 1275; Abdo et al. 2009c) and 104 blazars consisting of 58 FSRQs, 42 BL Lac objects, and 4 blazars with unknown classification based on their Spectral Energy Distribution (SED).

The radio-to-optical emission of luminous blazars of the FSRQ type is known to be produced by the synchrotron radiation of relativistic electrons accelerated within the outflow, while the inverse Compton (IC) scattering of low-energy photons by the same relativistic

electrons is most likely responsible for the formation of the high energy X-ray-to- $\gamma$ -ray component. In addition, it is widely believed that the IC emission from FSRQs is dominated by the scattering of soft photons external to the jet (external Compton radiation, ECR). These photons, in turn, are produced by the accretion disk, and interact with the jet either directly or indirectly, after being scattered or reprocessed in the broad-line region (BLR) or a dusty torus (DT; see, e.g., Dermer & Schlickeiser 1993; Sikora et al. 1994; Błażejowski et al. 2000). Other sources of seed photons can also contribute to the observed IC radiation, and these are in particular jet synchrotron photons through the synchrotron self-Compton process (hereafter SSC; Maraschi et al. 1992; Sokolov & Marscher 2005).

In this context, detailed X-ray studies offer a unique possibility for discriminating between different proposed jet emission models, since those scenarios predict distinct components to be prominent in blazar spectra around keV photon energies. For example, in the soft X-ray range a break is expected in the ECR/BLR model, tracking the low-energy end of the electron energy distribution (Tavecchio et al. 2000; Sikora et al. 2009). Indeed, both the *XMM-Newton* and the *Suzaku* X-ray data of RBS 315 show “convex” spectra (Tavecchio et al. 2007). Such a curvature, on the other hand, can be alternatively accounted for by an excess absorption below 1 keV over the Galactic value, or by an intrinsic curvature in the electron energy distribution. Furthermore, the situation can be more complex, with the simultaneous presence of yet additional components, such as the high-energy tail of the synchrotron continuum, SSC emission, or the narrow-band spectral feature originating from the “bulk Comptonization” of external UV (disk) radiation by cold electrons within the innermost parts of relativistic outflow (Begelman & Sikora 1987; Sikora & Madejski 2000; Moderski et al. 2004; Celotti et al. 2007).

Ghisellini et al. (1998) have studied the spectral energy distribution of 51 EGRET-detected  $\gamma$ -ray loud blazars and have applied the SSC+ECR model to the spectra of these sources. Although most of the broadband data collected by Ghisellini et al (1998) corresponded to non-simultaneous measurements, those authors discovered clear trends and correlations among the physical quantities obtained from the model calculations. In particular, they found an evidence for a well-defined sequence such that the observed spectral properties of different blazar classes (BL Lacs and FSRQs) can be explained by an increasing contribution of an external radiation field towards cooling jet electrons (thus producing the high-energy emission) with the increasing jet power. As a result, while the SSC process alone may account for the entire high-energy emission of low-power sources (BL Lacs), a significant contribution from the ECR is needed to explain the observed spectra of high-power blazars (FSRQs). Meanwhile, when focusing on one particular object, Mukherjee et al. (1999) reported that they found a similar trend in the different spectral states of PKS 0528+134. They studied the sequence of flaring and low-flux states of the source and found that the

SSC mechanism plays a more important role when the source is in a low state, and the ECR mechanism is the dominant electron cooling mechanism when the source is in a high  $\gamma$ -ray state (see in this context also Sambruna et al. 1997).

In order to understand the blazar phenomenon and the differences between BL Lacs and FSRQs, as well as the origin of spectral transitions in a particular object, one has to obtain truly simultaneous coverage across the entire spectrum, during both flaring and low-activity states. However, past  $\gamma$ -ray observations in low-activity states have been limited to only a few extremely luminous objects, such as PKS 0528-134 or 3C 279. Only now, with the successful launch of the *Fermi* satellite and the excellent performance of the *Suzaku* instruments, do we have an opportunity to study high-energy spectra of blazars with substantially improved sensitivity, and therefore can probe the different states of the sources’ activity.

In this paper, we report the high-sensitivity, broadband *Suzaku* observations of five FSRQs, namely PKS 0208–512, Q 0827+243, PKS 1127–145, PKS 1510–089, and 3C 454.3, which were bright gamma-ray sources detected by EGRET. Additionally, all of these sources were monitored simultaneously or quasi-simultaneously by the *Fermi* LAT and *Swift* Ultraviolet/Optical Telescope (UVOT; Roming et al. 2005). These broadband and high-sensitivity observations allow us to reveal the characteristics of the high-energy IC continuum in the low-activity states of luminous blazars. The paper is organized as follows: in §2, we describe observation and data reduction in the X-ray (*Suzaku*), UV-optical (*Swift* UVOT) and  $\gamma$ -ray (*Fermi* LAT) domains. In §3, we present the broad-band analysis results. Finally, in §4 we discuss the constraints on the jet parameters and speculate on the the origin of different activity states in luminous blazars. Throughout the paper we adopt the cosmological parameters  $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_M = 0.27$ , and  $\Omega_\Lambda = 0.73$ .

## 2. Observation and Data Reduction

### 2.1. *Suzaku*

Five FSRQs were observed by *Suzaku* (Mitsuda et al. 2007) for 40 ks each as one of the long-category projects between 2008 October and 2009 January. Table 1 summarizes the start time, end time, and the exposures for each observation. *Suzaku* carries four sets of X-ray telescopes (Serlemitsos et al. 2007), each with a focal-plane X-ray CCD camera (XIS, X-ray Imaging Spectrometer; Koyama et al. 2007) that is sensitive over the 0.3 – 12 keV band, together with a non-imaging Hard X-ray Detector (HXD; Takahashi et al. 2007; Kokubun et al. 2007), which covers the 10 – 600 keV energy band by utilizing Si PIN photo-diodes and GSO scintillation detectors. All of the sources were focused on the nominal center position

of the XIS detectors.

For the XIS, we used data sets processed using the software of the *Suzaku* data processing pipeline (ver. 2.2.11.22). Reduction and analysis of the data were performed following the standard procedure using the HEADAS v6.5 software package. The screening was based on the following criteria: (1) only ASCA-grade 0,2,3,4,6 events were accumulated, while hot and flickering pixels were removed using the CLEANSIS script, (2) the time interval after the passage of South Atlantic Anomaly was greater than 500 s, and (3) the object was at least  $5^\circ$  and  $20^\circ$  above the rim of the Earth (ELV) during night and day, respectively. In addition, we also selected the data with a cutoff rigidity (COR) larger than 6 GV. The XIS events were extracted from a circular region with a radius of  $4.2'$  centered on the source peak, whereas the background was accumulated in an annulus with inner and outer radii of  $5.4'$  and  $7.3'$ , respectively. We checked that the use of different source and background regions did not affect the analysis results. The response and auxiliary files were produced using the analysis tools XISRMFGEN and XISSIMARFGEN developed by the *Suzaku* team, which are included in the software package HEASoft version 6.5.

The HXD/PIN data (version 2.0) were processed with basically the same screening criteria as those for the XIS, except that we required  $\text{ELV} \geq 5^\circ$  through night and day and  $\text{COR} \geq 8$  GV. The HXD/PIN instrumental background spectra were provided by the HXD team for each observation (Kokubun et al. 2007; Fukazawa et al. 2006). Both the source and background spectra were made with identical good time intervals and the exposure was corrected for detector deadtime of 6.0 – 8.0%. We used the response files, version AE\_HXD\_PINHXDNOM5\_20080716.RSP, provided by the HXD team. In our analysis, the hard X-ray emission of PKS 1510–089 and 3C454.3 were detected in the energy range from 12 keV to 40 keV and 50 keV, respectively. For other objects, the sources were not detected in the HXD/PIN data. We also note here that all of the objects, the sources were not detected in the HXD/GSO data.

Table 1: *Suzaku* observation log of five FSRQs.

Object	$z$	Start time (UT)	Stop time (UT)	XIS/HXD exposures (ks)
0208–512	1.003	2008 Dec 14 07:33	2008 Dec 15 11:30	50.3/39.3
0827+243	0.939	2008 Oct 27 05:11	2008 Oct 28 08:04	35.3/36.3
1127–145	1.187	2008 Nov 29 18:10	2008 Nov 30 22:51	42.2/29.0
1510–089	0.361	2009 Jan 27 04:32	2009 Jan 28 05:25	38.5/36.2
3C454.3	0.859	2008 Nov 22 09:19	2008 Nov 23 16:31	39.9/40.4

## 2.2. *Swift*

Four analyzed FSRQs (PKS 0208–512, Q 0827+243, PKS 1510–089, and 3C 454.3) were observed with *Swift* between 2008 October and 2009 January, as part of *Swift* “target of opportunity” observations. We analyzed the data taken within or near the time of the *Suzaku* observations. For the case of PKS 1127–145, however, the observations were made only once in 2007 March. We focused on analysis of the UVOT data, since *Suzaku* provides much better photon statistics in X-rays than *Swift* X-ray Telescope (XRT; Burrows et al. 2005) and Burst Alert Telescope (BAT; Barthelmy et al. 2005), thanks to the long *Suzaku* exposures. We used the XRT data primarily for a consistency check regarding the spectral properties. Table 2 summarizes the start time, exposure time, and filters used for each observation.

The UVOT observing mode commonly takes an exposure in each of the six optical and ultraviolet filters (*v*, *b*, *u*, uvw1, uvm2, and uvw2) per *Swift* pointing. The list of UVOT observations is given in Table 2. For the screening, reduction and analysis of the *Swift* data, we used standard procedures within the HEASoft v.6.5 software package with the calibration database updated as of 2009 February 28. For this analysis, Level 2 sky-corrected image data were used. Since all sources were relatively bright, the source aperture sizes were chosen to correspond to those used to determine the UVOT zero points: 5'' for the optical and UV filters (Poole et al. 2008). The background was extracted from a nearby source-free circular region with 15'' radius. All image data were corrected for coincidence loss. The observed magnitudes were converted into flux densities by the standard procedures (Poole et al. 2008).

The XRT data were all taken in Photon Counting mode (PC mode; Hill et al. 2004). The data were reduced by the XRT data analysis task XRTPIPELINE version 0.12.0. Photons were selected from the event file by xselect version 2.4. The auxiliary response file was created by the XRT task XRTMKARF and the standard response file SWXPC0TO12S6\_20010101V011.RMF. All spectra were analyzed in the 0.3–10.0 keV band using XSPEC version 11.3.2.

## 2.3. *Fermi* LAT

During the first year of *Fermi* Large Area Telescope (LAT; Atwood et al. 2009) operation, most of the telescope’s time has been dedicated to “survey mode” observing, where *Fermi* points away from the Earth, and nominally rocks the spacecraft axis north and south from the orbital plane to enable monitoring of the entire sky every  $\sim 3$  hours (or 2 orbits). We analyzed the LAT’s observations of the five blazar regions using data collected during the first 4-5 months centered around *Suzaku* observations. Little variability indicated by the

<sup>a</sup>*Swift* XRT

<sup>b</sup>*Swift* UVOT

LAT lightcurves for the studied objects during this time implies that the constructed broad-band spectra, even though not exactly simultaneous, are representative for the low-activity states of all five blazars.

The data used here comprise all scientific data obtained between 4 August and 19 December 2008 for PKS 0208–512, Q 0827+243, PKS 1127–145 and 3C 454.3 (interval runs from Mission Elapsed Time (MET) 239557417 to 251345942), and 4 August 2008 and 30 January 2009 for 1510–089 (MET 239557417 to 254966035), respectively. We have applied the zenith angle cut to eliminate photons from the Earth’s limb, at 105°. This is important in pointed mode observations, but also important for survey mode due to overshoots and sun avoidance maneuvers. In addition, we excluded the time intervals when the rocking angle was more than 43°. We use the “Diffuse” class events (Atwood et al. 2009), which, of all reconstructed events have the highest probability of being photons.

In the analysis presented here, we set the lower energy bound to a value of 200 MeV, since the bin counts for photons with energies of  $\sim 100$  MeV and lower are systematically lower than expected based on extrapolations of a reasonable functions. Science Tools version v9r14 and IRFs (Instrumental Response Functions) P6\_V3 were used.

### 3. Results

#### 3.1. *Suzaku*

##### 3.1.1. *Temporal analysis*

Figure 1 shows the count rate variations of the five observed FSRQs. The summed XISs (XIS0,1,3) light curves are shown separately in different energy bands: 0.5–2 keV (*upper* panel), 2–10 keV (*middle* panel), and 0.5–10 keV (*bottom* panel), respectively. Since the count rate variations of the HXD/PIN detector were less clear due to limited photon statistics and uncertainty of the modeling of the non-X-ray background, we only concentrate on the temporal variability of the XIS data below 10 keV. We evaluate the fractional variability by calculating the variability amplitude relative to the mean count rate corrected for effects of random errors (e.g., Edelson et al. 2002):  $F_{\text{var}} = \sqrt{S^2 - \overline{\sigma_{\text{err}}^2}} / \bar{x}$ , where  $S^2$  is the total variance of the light curve,  $\overline{\sigma_{\text{err}}^2}$  is the mean error squared and  $\bar{x}$  is the mean count rate. The variability amplitude in the XIS bands are  $F_{\text{var}} = 0.036 \pm 0.021$  for 0208–512,  $F_{\text{var}} = 0.027 \pm 0.010$  for 1127–145, and  $F_{\text{var}} = 0.025 \pm 0.008$  for 1510–089, respectively. 0827+243 and 3C454.3 show only weak variability, which is not significant.

##### 3.1.2. *Time-averaged spectral analysis*

In the following we report the analysis procedure and results for each object. The background-subtracted spectra were fitted using XSPEC ver.11.3.2. All errors are quoted at the 90% confidence level for the parameter of interest unless otherwise stated. All the fits in this paper are restricted to the energy ranges of 0.5–10 keV (XIS0,3: the FI chips), 0.3–8 keV (XIS1: the BI chip), 12–40 keV for PKS 1510–089, and 12–50 keV for 3C 454.3 (HXD/PIN). We fixed the relative normalization of the XISs and HXD/PIN at 1.13, which is carefully determined from the XIS calibration using nominal pointings of the Crab Nebula. Serlemitsos et al. (2007) reported that spectral normalizations are slightly different (a few percent) among the CCD sensors based on a contemporaneous fit of the Crab spectra. Therefore, we adjusted the normalization factor among the three XISs relative to XIS0. The results of the spectral fits with a simple absorbed power-law model are summarized in Table 3 (with Galactic absorption) and Table 4.

Table 3: Results of the spectral fits to the *Suzaku* data using a power-law with Galactic absorption

Errors correspond to 90% confidence level.

<sup>a</sup>Fixed value indicates the Galactic absorption column density in units of  $10^{20} \text{ cm}^{-2}$ .

<sup>b</sup>Flux in units of  $10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ .

### PKS 0208–512

The time averaged, background subtracted three XIS spectra of PKS 0208–512, when fitted jointly, are well described by a single absorbed power-law model, and the absorption column is consistent with the Galactic value  $N_{\text{H}} = 3.08 \times 10^{20} \text{ cm}^{-2}$  (Dickey & Lockman 1990). We obtained the best fit photon index  $\Gamma = 1.68 \pm 0.02$  and the 2 – 10 keV flux  $F_{2-10\text{keV}} = (1.37 \pm 0.03) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$  with a chi-squared value of 0.91 for 250 dof. Figure 2 shows the spectra obtained with the XISs with residuals plotted against the best-fit power-law model with Galactic absorption. Although statistically acceptable, we notice that the residuals of the fits show moderate excess feature at low energies, below 1 keV.

In the previous observation with BeppoSAX during a high flux state (Tavecchio et al. 2002),  $F_{2-10\text{keV}} \sim 4.7 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$  - which is a factor of three larger than in our *Suzaku* observations - the X-ray spectrum is well described by a power-law with photon index  $\Gamma \sim 1.7$ , similar to the *Suzaku* result. However, Tavecchio et al. reported that the spectrum was heavily absorbed below 1 keV, indicating a column density of  $N_{\text{H}} = 1.67 \times 10^{21} \text{ cm}^{-2}$ . Figure 4 shows the *Suzaku* spectrum with residuals assuming such an increased value of  $N_{\text{H}}$ . The residuals indicate significant soft excess emission below 1 keV, if  $N_{\text{H}}$  is the same as found in the previous BeppoSAX observation.

The variable soft X-ray emission of PKS 0208–512 may indicate that the convex spectrum observed by BeppoSAX reflects an intrinsic IC continuum shape, while the soft excess observed by *Suzaku* reflects the presence of an additional spectral component which becomes prominent when the source gets fainter (see Tavecchio et al. 2007; Kataoka et al. 2008).

Table 4: Results of the spectral fits to the *Suzaku* data with best fit models

Object	Model <sup>a</sup>	$N_{\mathrm{H}}$	$\Gamma_{\mathrm{hi}}$ <sup>b</sup>	$\Gamma_{\mathrm{low}}$ <sup>c</sup>	$F_{2-10\mathrm{keV}}$ <sup>d</sup>	kT (keV)	$\chi^2_{\mathrm{r}}$

<sup>a</sup>Spectral fitting models. PL, power-law function; PL+PL, double power-law function; PL+BB, power-law + blackbody model.

<sup>b</sup>Differential spectral photon index.

<sup>c</sup>Differential spectral photon index at the low-energy X-ray band, when fitted with a double power-law function.

<sup>d</sup>Flux in units of  $10^{-12} \mathrm{erg cm}^{-2} \mathrm{s}^{-1}$ .

Therefore, to model in more detail the observed X-ray spectrum, we first considered a double power-law fit (PL + PL) in which the soft X-ray excess is represented by a steep power-law component. The absorption column is fixed at  $N_{\mathrm{H}} = 1.67 \times 10^{21} \mathrm{cm}^{-2}$ , as given by Tavecchio et al. (2002). We obtained the photon indices  $\Gamma_1 = 4.98 \pm 0.30$  and  $\Gamma_2 = 1.71^{+0.02}_{-0.04}$ . This provides an acceptable fit, with  $\chi^2_{\mathrm{r}}/\mathrm{dof} = 0.90/248$ . We also considered an alternative fit consisting of a power-law function and a blackbody component. This model also gives a similarly good representation of the data with  $\chi^2_{\mathrm{r}}/\mathrm{dof} = 0.90/248$ , implying  $\Gamma = 1.78 \pm 0.03$  and the temperature of the introduced thermal component of  $kT = 0.092 \pm 0.003 \mathrm{keV}$ . Both fits appear to be as good as a single power-law with free absorption, and do not improve the goodness of fit.

### Q 0827+243

The time averaged spectra of Q 0827+243 collected with the XISs are well fitted by an absorbed power-law model with a photon index  $\Gamma = 1.46 \pm 0.02$  ( $\chi^2_{\mathrm{r}} = 0.84$  for 194 dof). The absorption column is consistent with the Galactic value of  $N_{\mathrm{H}} = 3.62 \times 10^{20} \mathrm{cm}^{-2}$  (Dickey & Lockman 1990), and the flux over 2 – 10 keV is  $F_{2-10\mathrm{keV}} = (1.37 \pm 0.04) \times 10^{-12} \mathrm{erg cm}^{-2} \mathrm{s}^{-1}$ . As shown in Figure 2, there is no evidence for any additional spectral feature in the soft band. This result is in good agreement with previous *Chandra* observations of the core (Jorstad & Marscher 2004), revealing that the X-ray continuum is well described by a power-law model

( $\Gamma \sim 1.4$ ) with Galactic absorption.

### PKS 1127–145

We first fitted the XISs spectra with a single power-law model with a Galactic absorption of  $N_{\text{H}} = 3.83 \times 10^{20} \text{ cm}^{-2}$  (Murphy et al. 1996). We obtained the photon index of  $\Gamma = 1.41 \pm 0.01$ ,  $\chi^2_{\text{r}} = 1.01$  for 331 dof, but the residuals show a substantial deficit of photons at low energies (Figure 2). To investigate this deficit in more detail, we fitted the spectra with a single power-law and a free absorption model. This model represents well the spectra with the best chi-squared value of 0.82 for 330 dof (Figure 3), indicating that the column density is higher than the Galactic value at the 99.9% confidence level. For this model the photon index is  $\Gamma = 1.51 \pm 0.02$  and the unabsorbed X-ray flux is  $F_{2-10\text{keV}} = (3.36 \pm 0.05) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ . The best-fit column density is  $N_{\text{H}} = (1.08 \pm 0.09) \times 10^{21} \text{ cm}^{-2}$ , which is similar to the one found in previous *Chandra* and XMM-Newton observations ( $N_{\text{H}} \sim 1.2 \times 10^{21} \text{ cm}^{-2}$ ) during a high state with  $F_{2-10\text{keV}} \sim 6 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$  (Bechtold et al. 2001; Foschini et al. 2006). We note that the Galactic absorption and a broken power-law model also well represents the spectra with  $\chi^2_{\text{r}}/\text{dof}$  of 0.81/329. In this model, the spectrum below  $E_{\text{brk}} = 1.50 \pm 0.08 \text{ keV}$  is rather hard ( $\Gamma_1 = 1.10 \pm 0.05$ ), and the high energy photon index is  $\Gamma_2 = 1.50 \pm 0.02$ .

### PKS 1510–089

Figure 2 shows the XISs and HXD/PIN spectra of PKS 1510–089 (including residuals), plotted against the best-fit power-law model with Galactic absorption, using the overall X-ray data between 0.3 and 40 keV. The best fit photon index is  $\Gamma = 1.37 \pm 0.01$  and the unabsorbed X-ray flux is  $F_{2-10\text{keV}} = (6.31 \pm 0.07) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ . However, this model did not represent the spectra well yielding a chi-squared value of 1.06 for 407 dof. The residuals indicate some excess emission at low energies.

To represent the observed X-ray spectra, we tried the same analysis as for PKS 0208–512. We first fitted the data by a double power-law model with Galactic absorption. We obtained the photon indices  $\Gamma_1 = 2.84^{+0.50}_{-0.47}$  and  $\Gamma_2 = 1.26^{+0.04}_{-0.06}$ . This provides an acceptable fit, with  $\chi^2_{\text{r}}/\text{dof} = 0.96/405$ . The improvement of the chi-squared statistic is significant at more than the 99.9% confidence level when compared to the single power-law model. Next, we considered an alternative fit consisting of a power-law function and a blackbody component. This model also gives a good representation of the data, with  $\chi^2_{\text{r}}$  of 0.97 for 405 dof, indicating that the photon index is  $\Gamma = 1.32 \pm 0.02$  and the temperature of the introduced thermal component is  $kT = 0.15 \pm 0.02 \text{ keV}$ . This result is consistent with previous *Suzaku* ( $\Gamma = 1.24 \pm 0.01$ ; Kataoka et al. 2008) and BeppoSAX observations ( $\Gamma = 1.39 \pm 0.08$ ; Tavecchio et al. 2000).

3C 454.3

302

303 We first fitted the XISs and PIN spectra with a single power-law model with a Galactic  
 304 absorption of  $N_{\text{H}} = 7.24 \times 10^{20} \text{ cm}^{-2}$  (Murphy et al. 1996). We obtained the photon index of  
 305  $\Gamma = 1.41 \pm 0.01$  ( $\chi^2_{\text{r}} = 1.00$  for 1090 dof), but the residuals show some scatter around 1 keV.  
 306 To investigate this scatter in more detail, we fitted the spectra with a single power-law and  
 307 a free absorption model. This model represents well the spectra with the best chi-squared  
 308 value of 0.97 for 1089 dof, indicating that the column density is higher than the Galactic  
 309 value at the 99.9% confidence level. For this model the photon index is  $\Gamma = 1.51 \pm 0.02$  and  
 310 the unabsorbed X-ray flux is  $F_{2-10\text{keV}} = (3.36 \pm 0.05) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ .

311 In the case of 3C 454.3 we obtained the best fit to the XISs and HXD/PIN spectra  
 312 assuming an absorbed power-law model with a photon index of  $\Gamma = 1.61 \pm 0.01$  and a  
 313 column density of  $N_{\text{H}} = (9.07 \pm 0.35) \times 10^{20} \text{ cm}^{-2}$ , which is larger than the Galactic value  
 314 at the 99.9% confidence level. The unabsorbed 2 – 10 keV flux is  $F_{2-10\text{keV}} = (1.66 \pm 0.01) \times$   
 315  $10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$  (Figure 2). The spectra can be fitted with both the Galactic absorption  
 316 and a broken power-law model as well as the above model ( $\chi^2_{\text{r}}/\text{dof}$  of 0.96/1088). In the  
 317 former case, the photon indices are  $\Gamma_1 = 1.47^{+0.01}_{-0.03}$  and  $\Gamma_2 = 1.61 \pm 0.01$ , while the break  
 318 energy is  $E_{\text{brk}} = 1.29^{+0.08}_{-0.11} \text{ keV}$ . In addition, we reanalyzed the previous *Suzaku* data collected  
 319 in December 2007 during the high state (Donnarumma et al. 2010). The time averaged  
 320 XISs and HXD/PIN spectra was well described by a single absorbed power-law model with  
 321  $\Gamma = 1.64 \pm 0.01$ , implying the flux  $F_{2-10\text{keV}} = (3.09 \pm 0.02) \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ , which is  
 322 larger by a factor of two than the one found in our 2008 observations. The absorption column  
 323 also shows a higher value of  $N_{\text{H}} = (1.07 \pm 0.03) \times 10^{21} \text{ cm}^{-2}$ .

324 Figure 5 shows the unfolded spectra obtained in 2007 (high state) and 2008 (this work;  
 325 low state). The bottom panel shows the residuals by subtracting the spectra in the high  
 326 state from those in the low state. The excess emission at low energies is clearly visible in  
 327 the residuals.

328 The previous X-ray observations of 3C 454.3 often indicated some additional absorption  
 329 in excess to the Galactic value. For example, Villata et al. (2006) reported  $N_{\text{H}} = (1.34 \pm$   
 330  $0.05) \times 10^{21} \text{ cm}^{-2}$  in the *Chandra* data collected in May 2005, during the outburst phase  
 331 ( $F_{2-8\text{keV}} \sim 8.4 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ , which is  $\sim 5$  times higher than in our observation). An  
 332 even higher hydrogen column density was found by Giommi et al. (2006), when fitting the  
 333 April-May 2005 data taken by the *Swift* XRT ( $N_{\text{H}} \sim 2 - 3 \times 10^{21} \text{ cm}^{-2}$ ), and by Atari et al.  
 334 (2007, 2008), using the July and December 2006, and May 2007 data taken by XMM-*Newton*.  
 335 Assuming that the intrinsic absorption in 3C 454.3 is the same as reported in Villata et al.  
 336 (2006), we fit our *Suzaku* data first by a double power-law function, obtaining  $\Gamma_1 = 3.66^{+0.35}_{-0.33}$   
 337 and  $\Gamma_2 = 1.61 \pm 0.02$ . This provides an acceptable fit, with  $\chi^2_{\text{r}}/\text{dof} = 0.97/1088$ . Next

we consider an alternative fit consisting of a power-law and a blackbody component. This model gives a good representation of the data, with  $\chi^2_r/\text{dof} = 1.00/1088$ , a photon index of  $\Gamma = 1.65 \pm 0.01$ , and a temperature of  $kT = 0.105 \pm 0.004 \text{ keV}$ . However, the fitting results do not improve the goodness of fit compared with the single power-law model with free absorption.

### 3.1.3. Time-resolved spectral analysis

In order to investigate the X-ray spectral evolution of each object, we divided the total exposure into one-orbit intervals ( $\sim 5760 \text{ s}$ ). We fitted the overall XIS spectra between 0.3 and 10 keV with an absorbed simple power-law function. The photoelectric absorbing column densities were fixed at the values derived in §3.1.2. Figure 6 shows the relation between the 2 – 10 keV fluxes versus the photon indices measured by the *Suzaku* XISs. Significant spectral variation is seen in PKS 0208–512 ( $\Gamma = 1.4 - 1.8$ ), Q 0827+243 ( $\Gamma = 1.2 - 1.6$ ), PKS 1127–145 ( $\Gamma = 1.4 - 1.6$ ), and PKS 1510–089 ( $\Gamma = 1.3 - 1.5$ ). In the case of 3C 454.3, the X-ray photon index is only weakly variable around the mean value  $\Gamma \sim 1.6$ . Figure 6 clearly reveals a spectral evolution with the X-ray spectra hardening as the sources become brighter. Such a trend is often observed in high-frequency-peaked BL Lac objects (e.g., Kataoka et al. 1999), but it has never been observed so clearly in FSRQs (but see Kataoka et al. 2008 for PKS 1510–089).

## 3.2. *Swift*

Since the effective area of the *Swift* XRT is less than 10% of the *Suzaku* XIS in the 0.5–10 keV range, detailed spectral modeling is difficult using *Swift* data. Furthermore, the average exposure for the *Swift* observation was only a few kiloseconds, which was much less than the *Suzaku* exposure. We therefore fit the XRT data simply with a power-law model with Galactic absorption in the energy range 0.3–10 keV for the cross-calibration between the two instruments. The results of the spectral fits are summarized in Table 5. We can see that the results obtained with *Suzaku* and *Swift* are consistent within the range of error except PKS 1127–145.

The UVOT fluxes in each filter were corrected for Galactic extinction following the procedure described in Cardelli et al. (1989). We generated a list of the amount of extinction that needs to be accounted for in each filter,  $A_\lambda = E_{B-V}(aR_V + b)$ , where  $a$  and  $b$  are constants. The Cardelli procedure provides a good approximation to the UV-through-

Table 5: Results of the spectral fits to the *Swift* XRT data using a power-law with Galactic absorption

science tools GTLIKE. This fits the data to a source model, along with models for the uniform extragalactic and structured Galactic backgrounds. Photons were extracted from a region with a  $10^\circ$  radius centered on the coordinates of the position of each object. The Galactic diffuse background model is the currently recommended version (gll\_iem\_v02 <sup>1</sup>), with the normalization free to vary in the fit. The response function used is P6\_V3\_DIFFUSE.

For simplicity, we model the continuum emission from each source with a single power-law. It is likely that such a model might be too simple, as shown in the paper reporting spectra of bright Fermi blazars (Abdo et al. 2010), where the gamma-ray data suggest a steepening of the spectrum with energy, well-described as a broken power-law. However, here, we are reporting cases of blazars in low-level activity states and thus relatively faint, where fits to a broken power-law model would result in poorly constrained spectral parameters for a more complex model; furthermore, we note that the use of such more complex spectral model in the gamma-ray band does not alter our conclusions or significantly change the parameters in Table 10. The extragalactic background is assumed to have a power-law spectrum, with its spectral index and the normalization free to vary in the fit. From an unbinned GTLIKE fit the best fit photon indices are  $\Gamma = 2.33 \pm 0.05$  for PKS 0208–512,  $\Gamma = 2.62 \pm 0.35$  for Q 0827+243,  $\Gamma = 2.77 \pm 0.14$  for PKS 1127–145,  $\Gamma = 2.48 \pm 0.03$  for PKS 1510–089, and  $\Gamma = 2.51 \pm 0.02$  for 3C 454.3 (see also Table 8). Here only statistical errors are taken into

<sup>1</sup>This model is available for download from the Fermi Science Support Center, <http://fermi.gsfc.nasa.gov/ssc>.

account, and we report fluxes using spectra extrapolated down to 100 MeV. In the case of bright sources (PKS 1510–089 and 3C 454.3), we also analyzed the data collected during the *Suzaku* observing period to construct the simultaneous broad-band spectra spectra.

Table 9 summarizes the flux in seven energy bands obtained by separately running GTLIKE for each energy band; 200–400 keV, 400–800 keV, 800–1600 keV, 1600–3200 keV, 3200–6400 keV, 6400–12800 keV, 12800–25600 keV, respectively.

## 4. Discussion

### 4.1. Broad-Band Spectra spectral fits

We constructed the broad-band spectral energy distribution (SED) ranging from the radio to  $\gamma$ -ray bands for the five observed FSRQs, and these are shown in Figure 7. Here the filled red circles and solid lines represent simultaneous data from the UV/optical (*Swift* UVOT), X-ray (*Suzaku*) and  $\gamma$ -ray (*Fermi* LAT) observations. Quasi-simultaneous data are also shown as red open triangles and dashed lines. Historical radio (NED) and  $\gamma$ -ray (EGRET) data are also plotted as filled blue circles. Green symbols in the SEDs of PKS 1510–089 and 3C 454.3 denote the previous simultaneous observations (Kataoka et al. 2008; Donnarumma et al. 2010).

In order to model the constructed SEDs, we applied the synchrotron-inverse Compton

(IC) emission model described in Tavecchio & Ghisellini (2008), where both synchrotron and external (BLR and DT) photons are considered as seed radiation fields contributing to the IC process (SSC+ECR). The electron distribution is modeled as a smoothly broken power-law:

$$N'(\gamma) = K \gamma^{-n_1} \left(1 + \frac{\gamma}{\gamma_{\text{br}}}\right)^{n_1-n_2}, \quad (1)$$

where  $K$  (cm $^{-3}$ ) is a normalization factor,  $n_1$  and  $n_2$  are the energy indices below and above the break Lorentz factor  $\gamma_{\text{br}}$ . The electron distribution extends within the limits  $\gamma_{\text{min}} < \gamma < \gamma_{\text{max}}$ . We also assume that the ‘blazar emission zone’, with the comoving size  $R$  and magnetic field intensity  $B$ , is located at the distance  $r$  such that  $r_0 < r < r_{\text{BLR}} < r_{\text{DT}}$ , where  $r_0$  is the distance below which the photon energy density in the jet rest frame is dominated by the direct radiation of the accretion disk,  $r_{\text{BLR}}$  is the characteristic scale of the broad-line-region, and  $r_{\text{DT}}$  is the scale of the dusty torus (see the discussion in Tavecchio & Ghisellini 2008 as well as in Sikora et al. 2009). This choice, while somewhat arbitrary, has been validated by a number of authors modeling broad-band spectra of FSRQs. Hence, the comoving energy density of the dominant photon field — provided by the BLR — is

$$U'_{\text{rad}} \simeq \Gamma_j^2 \frac{\eta_{\text{BLR}} L_{\text{d}}}{4\pi r_{\text{BLR}}^2 c}, \quad (2)$$

where  $\Gamma_j$  is the jet bulk Lorentz factor, and the BLR is assumed to reprocess  $\eta_{\text{BLR}} \simeq 10\%$  of the disk luminosity  $L_{\text{d}}$ . Finally, we assume that the jet viewing angle is in all the cases  $\theta_j \simeq 1/\Gamma_j$ , so that the jet Doppler factor  $\delta_j \simeq \Gamma_j$ .

The results of model fitting are shown in different panels of Figure 7, and the resulting parameters are summarized in Table 10. In the context of this model, where we assume the

dissipation region to be between the immediate vicinity of the accretion disk but within the BLR, it is clear that in all cases the LAT fluxes are dominated by the IC/BLR component, while in the X-ray band both IC/BLR and IC/DT processes may contribute at a comparable level. In addition, the SSC emission seems negligible, being in particular too weak to account for the soft X-ray excess discussed in the previous sections. This excess, on the other hand, may be well represented by the high-energy tail of the synchrotron continuum, or an additional blackbody-type spectral component.

Table 10: Model parameters used to calculate the SEDs of five FSRQs

Object	$n_1$	$n_2$	$\gamma_{\min}$	$\gamma_{\text{br}}$	$\gamma_{\max}$	$K$ [ $10^4 \text{ cm}^{-3}$ ]	$\Gamma_j$	$R$ [ $10^{16} \text{ cm}$ ]	$B$ [G]	$L_d$ [ $10^{46} \text{ erg/s}$ ]	$r_{\text{BLR}}$ [ $10^{18} \text{ cm}$ ]	$r_{\text{DT}}$ [ $10^{18} \text{ cm}$ ]
0208–512	2	3.3	3.0	700	$4.3 \times 10^4$	2.2	15	1.8	1.1	1.5	0.76	3.0
0827+243	2	3.3	1.5	300	$1.0 \times 10^4$	8.5	10	1.8	3.8	2.0	1.3	4.2
1127–145	2	3.4	1.2	110	$5.0 \times 10^3$	0.65	10	6.5	4.1	10	0.8	10
1510–089	2	3.5	3.0	190	$4.6 \times 10^4$	0.81	13	4	0.8	0.3	0.48	4
3C 454.3	2	3.8	1.0	290	$3.0 \times 10^4$	4.5	12	3.2	0.8	4.0	1.5	30

Based on the model results, for each object we compute the ratio of the comoving energy densities stored in jet electrons and the magnetic field,

$$\frac{U'_e}{U'_B} = \frac{\int_{\gamma_{\min}}^{\gamma_{\max}} \gamma m_e c^2 N'(\gamma) d\gamma}{B^2/8\pi}, \quad (3)$$

where  $B$  is the magnetic field intensity in the emission region. In addition, we compute the implied total kinetic jet power as

$$L_j = \pi R^2 c \Gamma_j^2 (U'_e + U'_B + U'_p), \quad (4)$$

where  $R$  is the emission region linear size, and  $U'_p$  is the energy density of cold protons. The latter parameter is estimated assuming one proton per ten electron-positron pairs (see the discussion in Sikora et al. 2009), namely  $U'_p = 0.1 m_p c^2 \int_{\gamma_{\min}}^{\gamma_{\max}} N'(\gamma) d\gamma$ . The resulting total kinetic power of the outflow is then compared with the accretion luminosity (assuming standard accretion disk with 10% radiative efficiency), by means of the evaluated efficiency parameter  $\eta_j = L_j/L_{\text{acc}} \simeq L_j/10 L_d$ , where  $L_d$  is the disk luminosity implied by the model fitting (see Table 10). Note that with the above model assumptions and the model parameters inferred by us, the jets of objects considered here are dynamically dominated by cold protons,  $U'_p/U'_e \simeq 200/\langle\gamma\rangle > 1$ , since the mean Lorentz factor of the radiating ultra-relativistic electrons is in all the cases  $\langle\gamma\rangle \ll 200$  (see Table 11).

Table 11: Jet parameters of five FSRQs in low-activity states

Object	$U'_e/U'_B$	$L_j$ [ $10^{46}$ erg/s]	$\eta_j$	$\langle\gamma\rangle$
0208–512	2	0.8	0.06	16
0827+243	0.6	2.8	0.14	8
1127–145	0.03	5.8	0.06	5
1510–089	0.9	1	0.35	12
3C 454.3	7	9.4	0.23	5

Some of the derived jet parameters for five luminous blazars in their low-activity states are significantly different from the analogous parameters claimed for the flaring states, *even in the same object*. For example, in the case of the high-activity state of PKS 1510–089, Kataoka et al. (2008) estimated (under the same assumptions regarding the jet content as in this paper) the total kinetic power of the jet as  $L_j \sim 2.7 \times 10^{46} \text{ erg s}^{-1}$ , which is larger than the value derived in this paper, by about a factor of 3. In addition, our model values of the jet bulk Lorentz factors are also systematically lower than the ones given in the literature ( $\Gamma_j \simeq 10$  versus 20). Interestingly, other jet parameters, such as magnetic field intensity -  $B \simeq 1 \text{ G}$  - and the equipartition ratio,  $U'_e/U'_B \sim 1$ , or the general spectral shape of the electron energy distribution, are comparable to the ones found for flaring FSRQs, (albeit with a substantial scatter). It should be noted in this context, however, that for the three sources considered in this paper (namely PKS 1127–145, PKS 1510–089, and 3C 454.3), the flaring states were analyzed in a framework of the IC/DT model (Błażejowski et al. 2004, Kataoka et al. 2008, Sikora et al. 2008, respectively), while here, we argue that the IC/BLR contribution is dominant, as motivated by the detected relatively short (day) variability timescale of the X-ray continua. On the other hand, as discussed recently in Sikora et al. (2009), there is so-called a ‘conspiracy’ between the IC/BLR and IC/DT models, in a sense that the resulting inferred jet parameters are comparable in both cases. Hence, we can safely conclude that the low- and high-activity states of luminous blazar sources are due to the low and high total kinetic power of the jet, respectively, possibly related to varying bulk Lorentz factors within the blazar emission zone. And indeed, keeping in mind that the highly dynamical and complex jet formation processes in the closest vicinity of supermassive black holes – most likely shaped by accretion process subjected to several possible instability of the jet fuel, especially when the accretion rate is close to Eddington – such a significant variation in the total kinetic output of the outflow should not be surprising. Further support for this scenario comes from the fact that the jet efficiency factors estimated here,  $\eta_j \lesssim 1$ , are significantly lower than the ones found for powerful blazars in their flaring states (see Sambruna et al. 2006, Ghisellini et al. 2009), even if the difference in the jet proton content

adopted by various authors is taken into account.

## 4.2. Spectral Evolution

As shown in § 3.1.3, the X-ray spectra of the FSRQs analyzed here flatten with increasing flux. For  $\Gamma_j \sim \delta_j \sim 10$  and the dominant IC/BLR emission process, the electrons emitting the observed 1–10 keV photons have Lorentz factor  $\gamma \sim \gamma_{\min} \sim \text{few}$ . The electrons emitting X-ray photons in these sources are very low-energy, so cooling effects cannot play any role in the observed spectral evolution. In particular, it can be easily demonstrated that in a framework of our model (i.e., for the dominant IC/BLR energy losses), a strong cooling regime is expected only for the electrons with Lorentz factors greater than

$$\begin{aligned} \gamma_{\text{cr}} &\simeq \frac{3\pi m_e c^3 r_{\text{BLR}}^2}{\sigma_T R \Gamma_j^2 \eta_{\text{BLR}} L_d} \\ &\simeq 350 \left( \frac{r_{\text{BLR}}}{10^{18} \text{ cm}} \right)^2 \left( \frac{\eta_{\text{BLR}}}{0.1} \right)^{-1} \left( \frac{\Gamma_j}{10} \right)^{-2} \left( \frac{L_d}{10^{46} \text{ erg/s}} \right)^{-1} \left( \frac{R}{10^{16} \text{ cm}} \right)^{-1}. \end{aligned} \quad (5)$$

This, for the fitting parameters as given in Table 10, is typically above or just around the break Lorentz factor,  $\gamma_{\text{cr}} \gtrsim \gamma_{\text{br}}$  (in agreement with the discussion in Sikora et al. 2009). Adiabatic losses, if present, should not result in changing the slope of the power-law X-ray continua as well. Thus, one may suspect that the revealed spectral changes are shaped by the acceleration process within the blazar emission zone. In the case of relativistic jets the relevant acceleration processes are still quite uncertain, although, as pointed out by Kataoka et al. (2008) and Sikora et al (2009), the repeatedly observed flat X-ray photon indices  $\Gamma \leq 1.5$  seem to favor the mechanism discussed by Hoshino et al. (1992) for the low-energy segment of the electron energy distribution. In this model, the low-energy electrons (with Lorentz factors, roughly,  $\gamma < m_p/m_e$ ) are accelerated by a resonant absorption of the cyclotron emission generated by cold protons reflected from the shock front. As shown later by Amato & Arons (2006), the power-law slope of these accelerated electrons depends on the relative number of electrons to protons at the shock front. Hence, a larger fraction of the energy carried by jet protons during the higher-activity states should in principle result in a more efficient acceleration of jet electrons and their flatter spectrum, in agreement with the observed X-ray spectral evolution discussed here.

The above interpretation, on the other hand, would imply a significant variability in the  $\gamma$ -ray frequency range. Indeed, the broken power-law form of the electron energy distribution revealed by our spectral modeling discussed in the previous section implies the  $\gamma$ -ray flux

506  $F_\gamma \equiv [\nu F_\nu]_\gamma$  around the IC spectral peak  $\nu_\gamma \sim 10^{22}$  Hz should be, roughly

$$F_\gamma \simeq F_X \left( \frac{\nu_\gamma}{\nu_X} \right)^{2-\Gamma} \simeq 10^{4(2-\Gamma)} F_X, \quad (6)$$

507 where  $F_X$  is the monochromatic X-ray flux measured around  $\nu_X \sim 10^{18}$  Hz, and  $\Gamma$  is the  
 508 observed X-ray photon index. For example, our analysis for PKS 0208–512 indicates a  
 509 photon index  $\Gamma_1 \sim 1.8$  for an X-ray flux  $F_{X,1} \sim 1.2 \times 10^{-12}$  erg cm $^{-2}$  s $^{-1}$  in the lower state,  
 510 and  $\Gamma_2 \sim 1.5$  for  $F_{X,2} \sim 1.6 \times 10^{-12}$  erg cm $^{-2}$  s $^{-1}$  in the higher state. Thus, if the observed X-  
 511 ray variability is due to flattening of the electron energy distribution during the acceleration  
 512 process, one should observe the  $\gamma$ -ray variability of the order of

$$\frac{F_{\gamma,2}}{F_{\gamma,1}} \simeq 10^{4(\Gamma_1-\Gamma_2)} \frac{F_{X,2}}{F_{X,1}} \sim 20. \quad (7)$$

513 However, during the simultaneous *Fermi* observation, no significant  $\gamma$ -ray variability was  
 514 observed for the analyzed sources, at least within one day timescale.

515 Therefore, the most viable explanation for the observed X-ray spectral evolution is that  
 516 the IC power-law slope remains roughly constant during the flux variations, but the amount  
 517 of contamination from the additional soft X-ray component increases at low flux levels,  
 518 affecting the spectral fitting parameters at higher photon energies ( $> 2$  keV). Note that in  
 519 such a case the expected gamma-ray variability should be of the same order as the X-ray  
 520 variability, namely  $F_{\gamma,2}/F_{\gamma,1} \simeq F_{X,2}/F_{X,1} \sim 1.3$ .

521 We finally note in this context that, as shown in §3.1.2, the previous BeppoSAX data  
 522 for PKS 0208–512 collected during the high state indicated a convex X-ray spectrum, and  
 523 an excess absorption below 1 keV with a column density of  $N_H \sim 1.67 \times 10^{21}$  cm $^{-2}$  exceeding  
 524 the Galactic value by more than a factor of 5. However, the X-ray photon index was similar  
 525 to the one implied by our *Suzaku* observations ( $\Gamma \sim 1.7$ ). Therefore, the convex spectrum  
 526 observed by BeppoSAX may reflect an intrinsic shape of the IC emission involving the low-  
 527 energy cut-off in the electron energy distribution around  $\gamma \sim 1$ , as expected in the EC/BLR  
 528 model (Tavecchio et al. 2007), which is only diluted during the low-activity states due to  
 529 the presence of an additional soft X-ray spectral component.

530 Similar trend has been observed in 3C 454.3. To illustrate this, in Figure 8 we selected  
 531 the data which have a similar power-law slope ( $\Gamma \sim 1.6$ ) and plotted the absorption column  
 532 versus 2–10 keV flux densities derived from the *Chandra* (Villata et al. 2006), *Swift* (Giommi  
 533 et al. 2006), *XMM-Newton* (Raiteri et al. 2007, 2008), and *Suzaku* (this work) observations.  
 534 We can see that there is a trend of increasing the absorption value with source brightness, as  
 535 previously reported by Raiteri et al. (2007; 2008). These results may again be explained by

the soft excess emission being more important when the source gets fainter, and becoming almost completely “hidden” behind the hard X-ray power-law when the source gets brighter.

From the spectral fitting of the *Suzaku* data, we showed in §3.1.2 that the soft X-ray excess may be represented either by a steep power-law ( $\Gamma \sim 3 - 5$ ) or a blackbody-type emission ( $kT \sim 0.1 - 0.2$  keV). Since the synchrotron peak of each source is located around optical photon energies (see Figure 7), the high-energy synchrotron tail may possibly account for the observed soft X-ray excess emission, especially if being modified by the Klein-Nishina effects (see the discussion in Sikora et al. 2009 and Kataoka et al. 2008). On the other hand, the bulk-Compton spectral component produced by Comptonization of the UV accretion disk by cold electrons in the innermost parts of relativistic jets (e.g., Begelman & Sikora 1987) is a natural explanation for the apparent soft X-ray excess component.

## 5. Conclusions

We have presented the observations and analysis of the data for the  $\gamma$ -ray-loud blazars, PKS 0208–512, Q 0827+243, PKS 1127–145, PKS 1510–089, and 3C 454.3, obtained with the *Suzaku*, *Swift* UVOT and *Fermi* LAT. Observations were conducted between 2008 October and 2009 January. These observations allowed us to construct broadband spectra of the sources in the low  $\gamma$ -ray activity state, covering optical to GeV photon energy range. Our results are as follows:

1. The X-ray spectra of five FSRQs are well represented by an absorbed hard power-law model ( $\Gamma \sim 1.4 - 1.7$ ). For PKS 0208–512, PKS 1127–145, and 3C 454.3, the fitted absorption column is larger than the Galactic value (but we note that the “excess absorption” is not a unique representation of X-ray spectra of those blazars). Compared with previous X-ray observations, we see a trend of increasing apparent X-ray absorption column with increasing high-energy luminosity of the source.
2. *Suzaku* observations reveal spectral evolution of the X-ray emission: the X-ray spectrum becomes harder as the source gets brighter. Such spectral changes are most likely due to the underlying and steady low-energy spectral component which becomes prominent when the inverse-Compton emission gets fainter. This soft X-ray excess can be explained as a contribution of the high-energy tail of the synchrotron component, or bulk-Compton radiation.
3. We adopt the location of the blazar emission region to be outside of the immediate vicinity of the accretion disk but within the BLR, and within the context of this

model, we find that the contribution of the synchrotron self-Compton process to the high-energy radiative output of FSRQs is negligible even in their low-activity states.

4. We argue that the difference between the low- and high-activity states in luminous blazars is due to the different total kinetic power of the jet, most likely related to varying bulk Lorentz factor of the outflow within the blazar emission zone.

The *Fermi* LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique / Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden.

Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France.

LS was partially supported by the Polish Ministry of Science and Higher Education through the project N N203 380336.

Fig. 1.— Light curves of five FSRQs: 0.5 – 2 keV (*upper panels*), 2 – 10 keV (*middle panels*), and 0.5 – 10 keV (*bottom panels*). All the light curves were binned at 5760 s, corresponding to the period of the *Suzaku* orbit.

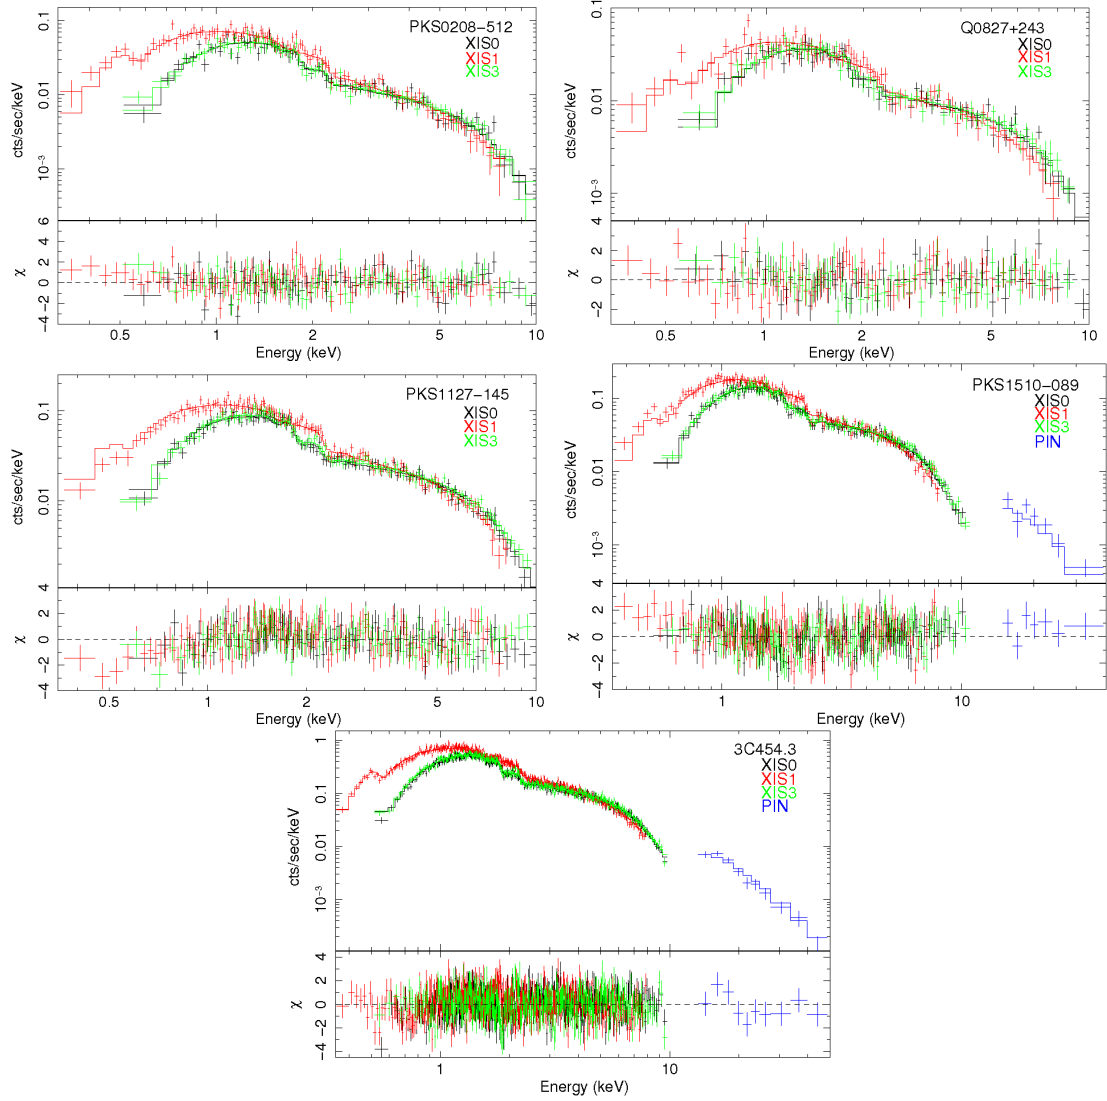

Fig. 2.— *Suzaku* spectra of five FSRQs: the top panel shows the data, plotted against a power-law model with the Galactic absorption. The bottom panel shows the residuals for the power-law fit. For 0208–512 and 1510–089, the data below 1 keV are in excess to the model. On the other hand, for 1127–145, the residuals show a substantial deficit of photons at low energies. For 3C454.3, some scatter around 1 keV in the residual panel is seen.

Fig. 3.— Best fit *Suzaku* spectrum of PKS 1127–145, PKS 1510–089 and 3C454.3. The top panel shows the data, plotted against an absorbed power-law model. The bottom panel shows the residuals to the power-law fit.

Fig. 4.— *Suzaku* spectrum of PKS 0208–512, with residuals assuming a column density of  $N_{\text{H}} \sim 1.67 \times 10^{21} \text{ cm}^{-2}$ . Deviations due to soft excess emission can be clearly seen.

Fig. 5.— Unfolded spectra of 3C 454.3 obtained in 2007 (high) and 2008 (low), respectively. The bottom panel shows the residuals by subtracting the spectra in the high state from those in the low state.

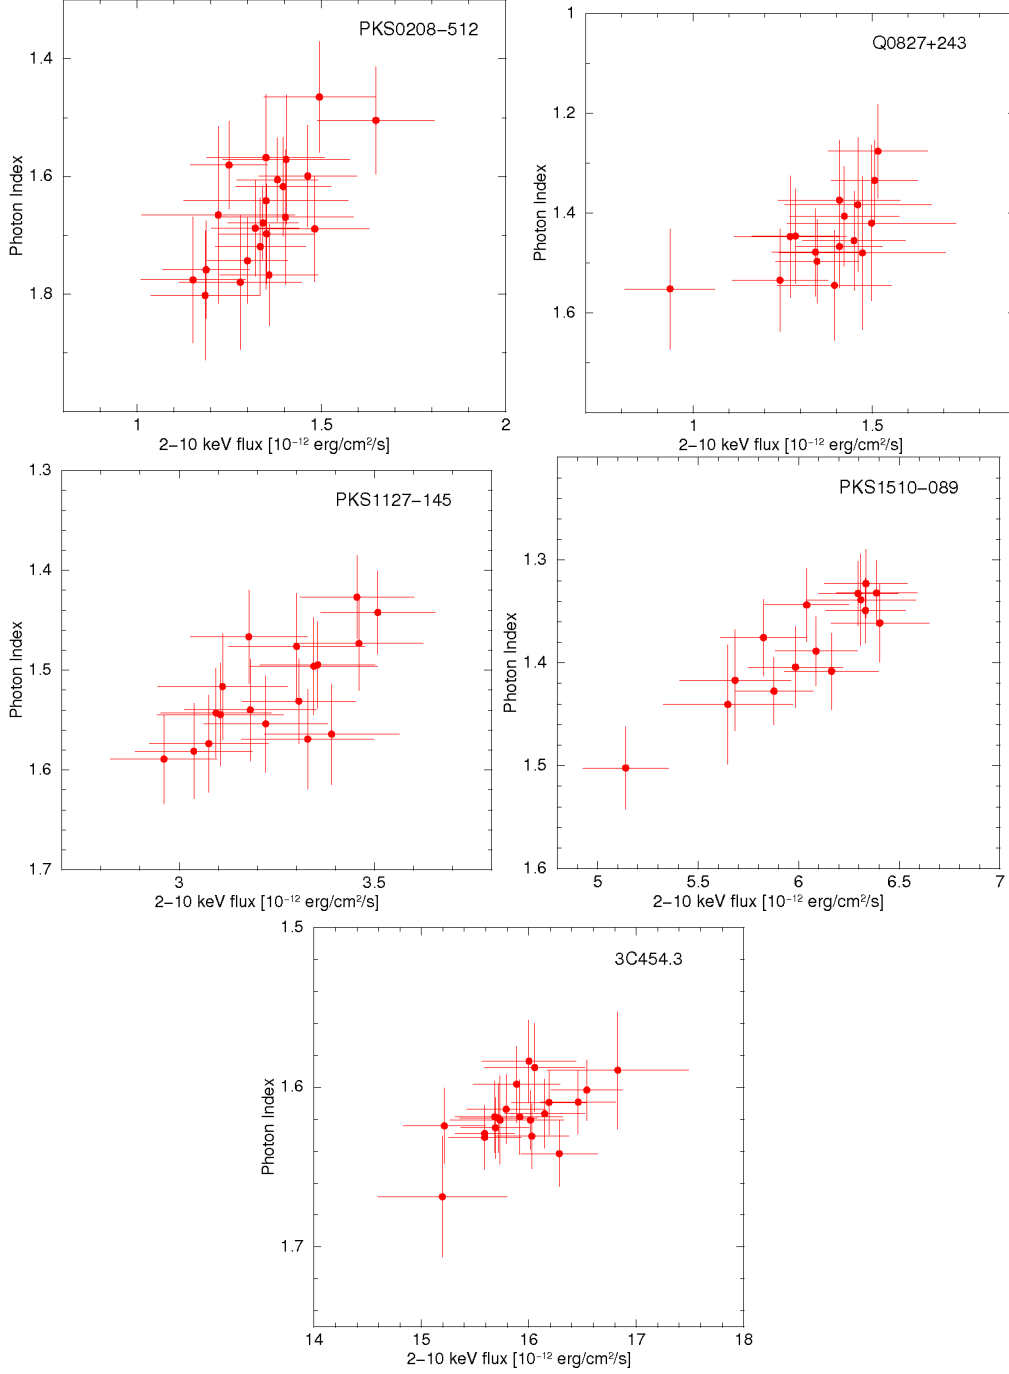

Fig. 6.— Correlation of the 2 – 10 keV flux vs. photon index of five blazars as measured by the *Suzaku* XISs.

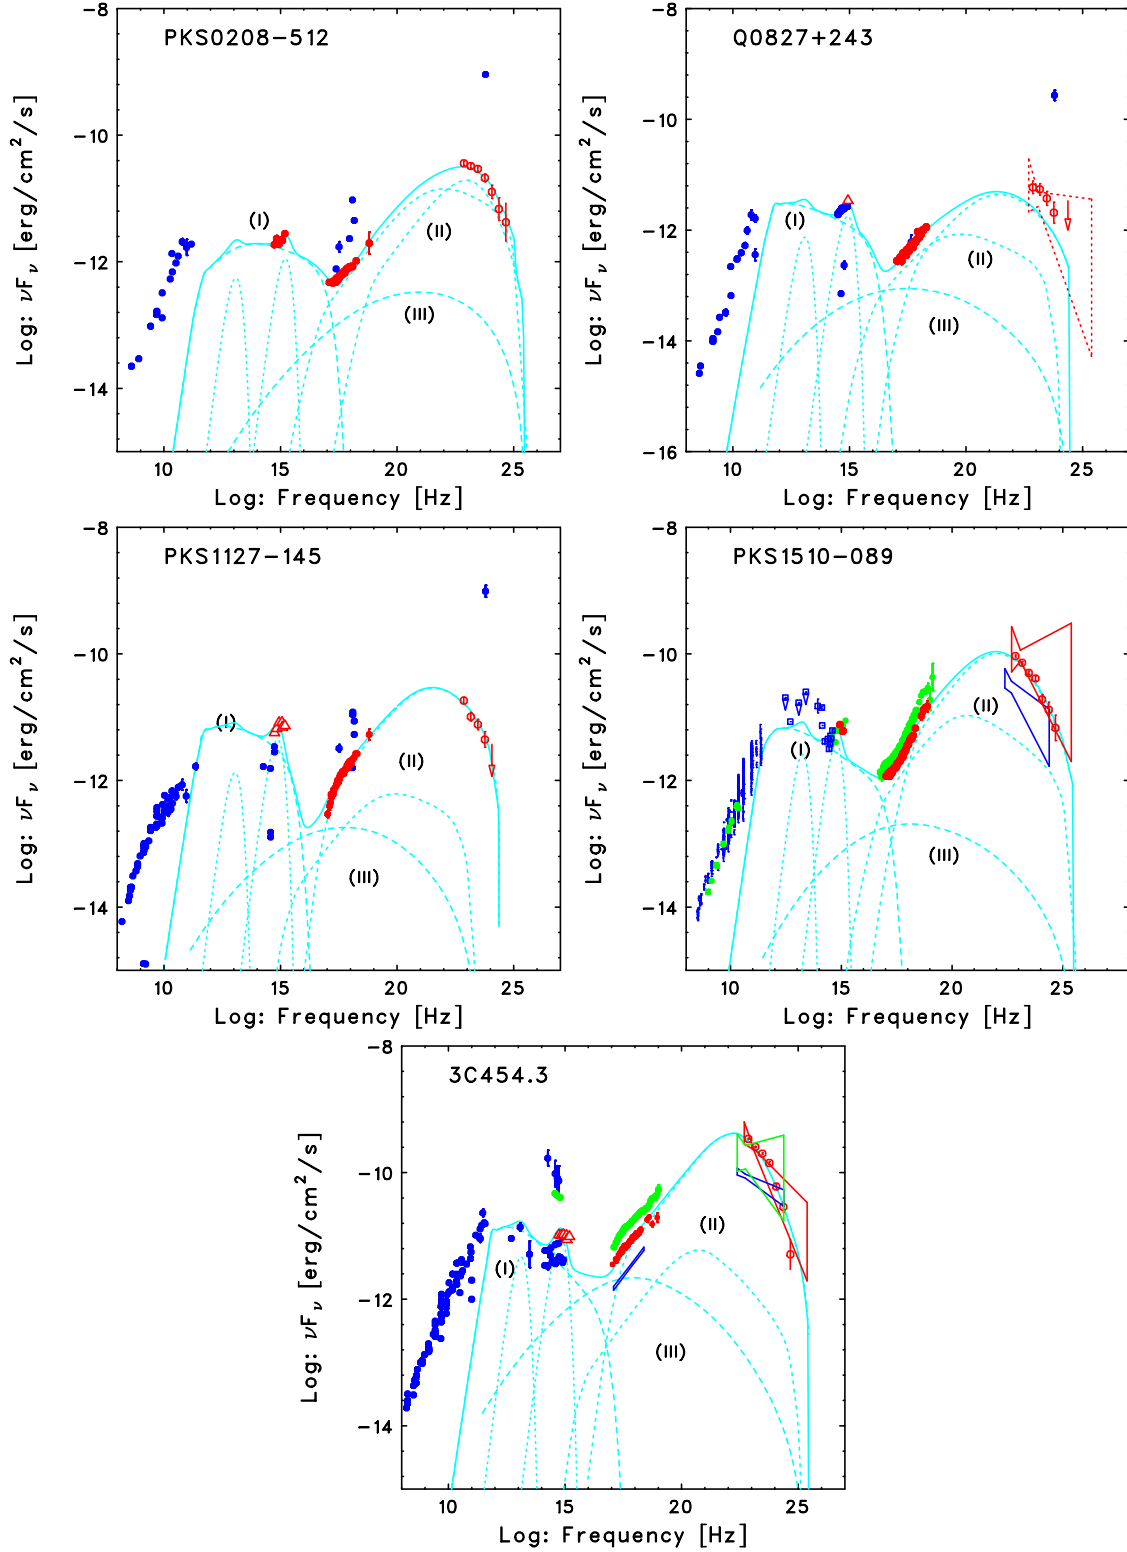

Fig. 7.— Overall SED of five sources constructed with broad-band data obtained during 2008 October to 2009 January (filled red circles and solid bow-tie). Quasi simultaneous data are also shown (open red circles). Historical radio (NED) and  $\gamma$ -ray (EGRET) data are also plotted as filled blue circles. Green symbols in the SEDs of PKS 1510–089 and 3C 454.3 denote the previous simultaneous observations (Kataoka et al. 2008; Donnarumma et al. 2010). The dotted lines show (I) the synchrotron and (II) the EC components, and (III)

Fig. 8.— Fluxes in the 2 – 10 keV band for different observations of 3C 454.3 vs.  $N_H$  for the fits with an absorbed power-law model. The dashed line indicates the Galactic absorption column. This figure indicates that the intrinsic X-ray spectrum is not a simple power-law, but instead, it shows some curvature, which may depend on the X-ray brightness.
